

KIC 8462852 FADED THROUGHOUT THE *KEPLER* MISSION

BENJAMIN T. MONTET^{1,2} AND JOSHUA D. SIMON³

(Dated: August 5, 2016)
Draft version August 5, 2016

ABSTRACT

KIC 8462852 is a superficially ordinary main sequence F star for which *Kepler* detected an unusual series of brief dimming events. We obtain accurate relative photometry of KIC 8462852 from the *Kepler* full frame images, finding that the brightness of KIC 8462852 monotonically decreased over the four years it was observed by *Kepler*. Over the first ~ 1000 days, KIC 8462852 faded approximately linearly at a rate of $0.341 \pm 0.041\%$ yr⁻¹, for a total decline of 0.9%. KIC 8462852 then dimmed much more rapidly in the next ~ 200 days, with its flux dropping by more than 2%. For the final ~ 200 days of *Kepler* photometry the magnitude remained approximately constant, although the data are also consistent with the decline rate measured for the first 2.7 yr. Of a sample of 193 nearby comparison stars and 355 stars with similar stellar parameters, 0.6% change brightness at a rate as fast as 0.341% yr⁻¹, and none exhibit either the rapid decline by $> 2\%$ or the cumulative fading by 3% of KIC 8462852. We examine whether the rapid decline could be caused by a cloud of transiting circumstellar material, finding while such a cloud could evade detection in sub-mm observations, the transit ingress and duration cannot be explained by a simple cloud model. Moreover, this model cannot account for the observed longer-term dimming. No known or proposed stellar phenomena can fully explain all aspects of the observed light curve.

Subject headings: stars: individual (KIC 8462852), stars: variables: general, circumstellar matter, techniques: photometric, methods: data analysis

1. INTRODUCTION

In addition to its primary mission of detecting exoplanets (Borucki et al. 2010), the *Kepler* satellite’s exquisite photometry has allowed groundbreaking studies in stellar astrophysics. Most notably, analyses of the seismic modes of stellar lightcurves have enabled otherwise inaccessible measurements of stellar ages, masses, evolutionary states, and internal structure (e.g., Bedding et al. 2011; Mosser et al. 2012; Bastien et al. 2013; Chaplin et al. 2014; Silva Aguirre et al. 2015). *Kepler* data are also providing fundamental new insights into mass loss on the red giant branch (e.g., Miglio et al. 2012), the variation of stellar rotation and stellar dynamos with age (e.g., Meibom et al. 2015; Barnes et al. 2016; van Saders et al. 2016), and the origin of the Blazhko effect in RR Lyrae variables (e.g., Szabó et al. 2010).

One of the most confounding *Kepler* discoveries is the light curve of KIC 8462852. First presented by Boyajian et al. (2016), KIC 8462852 appears to be a typical F3V star (Lisse et al. 2015). However, its light curve exhibits 10 significant dips over the timespan of the *Kepler* mission. These dips are irregular in shape, aperiodic, and vary in depth from fractions of a percent up to 20% of the total flux of the star. While the dips as a whole do not obey an obvious periodicity, a subset of them are consistent with a period of ~ 48 d, although some of those are 180° out of phase with the others. Boyajian et al. present several physical models to account for these dip-

ping events, concluding that a large family of exocomets or planetesimal fragments orbiting the star could plausibly explain the data.

KIC 8462852 quickly became the focus of considerable attention. Thompson et al. (2016) place tight constraints on the circumstellar dust around KIC 8462852 from millimeter and sub-millimeter observations, ruling out the planetesimal fragment hypothesis; Marengo et al. (2015) reach the same conclusion from an analysis of warm *Spitzer* data. Bodman & Quillen (2016) model the light curve with a swarm of comets. They find that the KIC 8462852 light curve in Quarters 16 and 17 of the *Kepler* mission can be explained by approximately 100 comets in a very tight cluster. This model, however, is unable to match the earlier dips in the light curve. Wright et al. (2016) proposed that the star may make an ideal target for SETI programs. As of yet, SETI searches in the optical (Schuetz et al. 2016; Abeysekera et al. 2016) and radio (Harp et al. 2016) have only resulted in null detections.

Other studies have made use of archival observations of KIC 8462852. Schaefer (2016) analyzed photographic plates from the “Digital Access to a Sky Century @ Harvard” (DASCH) archive (Grindlay et al. 2009; Laycock et al. 2010), obtained between 1890 and 1989. This work found KIC 8462852 to be dimming at an average rate of 0.165 ± 0.013 mag century⁻¹, or $0.152 \pm 0.012\%$ yr⁻¹. This result was quickly called into question. Both Hippke et al. (2016) and Lund et al. (2016) suggest that the observed dimming is the result of systematics in the DASCH data, particularly the Menzel Gap of the 1950s, and report the flux of KIC 8462852 to be consistent with no change over the baseline of the DASCH plates.

If the star is dimming with time, then a survey with a long time baseline and high photometric precision

² Harvard-Smithsonian Center for Astrophysics, Cambridge, MA 02138, USA

³ Observatories of the Carnegie Institution of Washington, 813 Santa Barbara St., Pasadena, CA 91101, USA

would be able to detect this variation. Modern ground-based imaging surveys generally operate over timescales of ~ 5 yr, and they lack the photometric accuracy to detect the ~ 8 mmag variation that would be expected from the analysis of the DASCH data by Schaefer (2016). The best-calibrated existing surveys, SDSS and Pan-STARRS (Magnier et al. 2013; Finkbeiner et al. 2016), would need a time baseline ~ 5 times as long in order to measure such a brightness change at 5σ significance (ignoring that stars as bright as KIC 8462852 with $V = 11.7$ are badly saturated in such data sets). Data from the *Kepler* mission, however, provide exactly such an opportunity.

Absolute photometry or long time-baseline photometry with typical *Kepler* data is difficult. Since *Kepler* was designed to detect and characterize events with timescales of minutes to hours, conventional pipelines to process *Kepler* photometry (including the official *Kepler* data processing pipeline) treat low frequency signals as spacecraft systematics and remove them (e.g., Jenkins et al. 2010; García et al. 2011). Any much slower fading or brightening of a star is not detectable with these algorithms by construction. During the creation of *Kepler* light curves as delivered to the data archive hosted by MAST, signals with periods longer than 30 days are overfit by the pipeline, destroying astrophysical signals such as stellar rotation-induced flux variations (e.g., Basri et al. 2010; Nielsen et al. 2013). To preserve long-term trends in the *Kepler* light curves, one must work with the raw pixel-level data delivered by the telescope.

Photometry with the pixel-level data has its own difficulties. Aperture photometry is complicated as the apertures around each star recorded by the telescope and downlinked to Earth are often smaller than the full point spread function (PSF) of the star (Bryson et al. 2010). Small deviations in the pointing of the telescope can then cause large variations in the total flux recorded inside the photometric aperture as the edges of the star’s PSF move relative to the edge of the downloaded set of pixels. Instead, one could consider modeling the PSF of the star on the detector. While possible in some cases (e.g., Rappaport et al. 2014), the lack of a reliable flat field for the *Kepler* detector array and the lack of background “sky” pixels make PSF modeling difficult, and nearly impossible for saturated stars ($K_p < 12$, Szabó et al. 2010).

An alternative approach to search for long-term linear trends is to leverage the full-frame images (FFIs) collected during the *Kepler* mission. At the beginning of the mission, *Kepler* recorded a series of eight FFIs over two days. It then continued to record one FFI each month throughout the mission (Haas et al. 2010). As *Kepler* rotated by 90° every three months, there are generally three consecutive FFIs with all stars located on the same pixels. A star then cycles through four different detectors over the course of a year, returning to its original position and repeating the cycle a year later. Because there are ~ 13 observations with any given star landing on the same pixels, accurate relative photometry can be obtained without flatfielding. The FFIs have been used to study stellar variability in RR Lyrae stars in the *Kepler* field (Kinemuchi 2011), highlighting their utility for photometry.

The primary *Kepler* mission lasted four years. A star dimming at a linear rate of 0.165 mag century $^{-1}$ ($0.152 \pm 0.012\%$ yr $^{-1}$), as has been purported for KIC

8462852 (Schaefer 2016), would be expected to decrease in brightness by 0.6% over the *Kepler* baseline, well above the photometric precision of the telescope. By analyzing the FFI data, one could avoid the removal of this trend by the data processing pipeline and the loss of flux from limited apertures in the raw pixel-level data. In this study, we attempt to characterize the long-term photometric behavior of KIC 8462852 through an analysis of *Kepler* FFI data.

This paper is organized as follows. In Section 2, we describe our data analysis and photometry. In Section 3, we present our results. In Section 4, we compare our results to a similar analysis of stars nearby KIC 8462852 on the detector and stars with similar stellar properties. In Section 5, we rule out instrumental effects that could be responsible for apparent brightness changes and consider whether background contamination, a transiting cloud of material, or a polar spot can explain the observed FFI light curve. We present our conclusions in Section 6.

2. DATA ANALYSIS

We downloaded all 53 FFI images from the Mikulski Archive for Space Telescopes (MAST) and sorted by the season in which they were collected. In this work, we use the “cal” frames, which have been calibrated from the raw data (Caldwell et al. 2010; Jenkins et al. 2010; Quintana et al. 2010). Specifically, these frames have had a bias level and dark current subtracted, the smear from CCDs being illuminated during readout corrected, the gain divided, and a flat field correction applied. We remove one frame, 2009170043915, as it was collected with the spacecraft mispointed by four pixels on the sky, making calibration with the other frames in that spacecraft orientation infeasible. For the remaining 52 frames, we first select a 120×120 pixel (8 arcmin square) region of the detector centered on the target star (Figure 1).

FIG. 1.— “Postcard” region of the *Kepler* detector surrounding KIC 8462852, located at the center of the image. In red is the aperture used for measuring the photometry from this star in all frames. The seven blue apertures represent the reference stars used for comparison photometry. The frame is aligned to match the orientation of the telescope, with North rotated approximately 25 degrees from pointing up.

We begin our processing by masking any saturated stars. While *Kepler* was designed with preservation of

FIG. 2.— Zoomed region of Figure 1 centered on KIC 8462852. In blue is the aperture used for measuring the photometry from this star in all frames. In purple is the postage stamp downloaded for the creation of the long cadence light curve for this star, while in red are the actual pixels used in the creation of the SAP and PDC light curves in Quarter 0 of the mission. The pixel response function is wider than the regions downloaded at 30-minute cadence, so not all of the flux from KIC 8462852 is captured. The orientation here is the same as in Figure 1.

photometry of saturated stars in mind, recovering the absolute brightness of these stars requires careful placement of photometric apertures, making automated procedures challenging. We then identify the ten brightest nearby stars in the subframes based on their brightest central pixel.

For all selected stars, including our target, we perform aperture photometry. The *Kepler* telescope is defocused to produce an image with a full-width at half-maximum of 1.5 pixels in diameter. However, due to the location of KIC 8462852 in the corner of the *Kepler* field, the Schmidt optics of the telescope produce a non-Gaussian and asymmetric PSF for each star (Bryson et al. 2010). As can be seen in Figure 2, these PSFs are several pixels in size and extend well beyond the pixels downloaded at 30-minute cadence during standard *Kepler* observations. To collect all the flux from the star, we then create 11×11 pixel apertures centered on the brightest pixel of each star.

Not all of these stars may be appropriate as calibration stars for relative photometry; some may be intrinsically variable, while others may be too faint to reliably obtain accurate photometry in each single exposure. We discard all stars with a standard deviation of the residuals from a linear fit to the data larger than 0.5%. Such a cut removed one bright star near KIC 8462852 (KIC 8462738) with periodic variations at the $> 5\%$ level as well as the two faintest stars in the sample, where photon noise prohibited accurate relative photometry, leaving us with seven reference stars.

We then determine the flux level of KIC 8462852 by comparing its aperture photometry to the aperture photometry recorded from the calibrator stars, weighted by the signal to noise ratio of each of the calibration stars. We use the standard deviation of the flux measured among all observations recorded on that particular pixel as the uncertainty associated with each observation. This value can vary by as much as a factor of two from detec-

tor to detector, in line with previous analyses of the noise in the primary *Kepler* mission (Gilliland et al. 2010).

Finally, we combine the data from each separate channel on the telescope. Because of the uncertainty in the underlying flat field, we allow for a linear offset term between each channel, so that if the sensitivity of one particular channel is lower than the others, our model would not try to model that signal is actual astrophysical variation. In practice, this requires fitting three parameters defining the offset for each channel relative to the first channel. The results are shown in Figure 3 and Table 1. For the purposes of plotting Figure 3 we must choose a particular set of offsets. We choose the maximum likelihood model of a linear fit to the first three years of data from the *Kepler* mission, which minimizes the scatter from quarter to quarter. In our analysis of any long-term dimming, we allow the offset terms to float as free parameters.

3. RESULTS

3.1. A Long-Term Dimming

From Figure 3, three main features are apparent. The first is a long-term dimming at a linear rate from the beginning of the *Kepler* mission until approximately Quarter 13. The dimming then increases rapidly such that the observed flux from the star decreases by approximately 2.5% over 200 days. For the final 200 days of the *Kepler* mission, the light curve flattens out, either returning to the original rate of decay or remaining constant.

In the primary *Kepler* mission, data were collected in four orientations as the telescope rolled every 93 days to keep its heat shield pointed at the sun. As a result, data for each star are collected on four different pixels, each for three months of every year. Therefore, we can separate many instrumental effects caused by a faulty pixel on the detector from astrophysical phenomena by looking for the same trends when only considering data from each specific orientation. In practice, we allow for a linear offset between the observed fluxes recorded on each individual module, reflecting our uncertainty about the underlying flat field of the detector itself. We note these results are apparent in data from each individual detector, not just the combined light curve, suggesting that the decline in flux is an astrophysical effect rather than an instrumental one, as discussed more fully in Section 5.

We fit a line to the first region of data, from the beginning of the mission until $\text{MJD}-2454833 = 1170$, encompassing 39 data points. We allow the relative offset between each detector to vary, three in total. It is possible that the recorded measurement uncertainties are not representative of the actual uncertainties. To account for a possible systematic underestimation of the uncertainties, we allow for an extra uncertainty term applied to data from each detector to be added in quadrature to our recorded uncertainties estimated from the data themselves, so that the i th data point recorded on the q th data channel has uncertainty $s_{i,q}$ such that

$$s_{i,q} = \sqrt{\sigma_i + j_q}. \quad (1)$$

Here, σ_i is the recorded uncertainty for the i th observation and j_q is the level of underestimation of the photometric uncertainty in quarter q , similar to the concept of

FIG. 3.— Photometry of KIC 8462852 as measured from the FFI data. The four colors and shapes (green squares, black circles, red diamonds, and blue triangles) represent measurements from the four separate channels the starlight reaches as the telescope rolls. The four subpanels show flux from each particular detector individually. The main figure combines all observations together; we apply three linear offsets to the data from different channels to minimize the scatter to a linear fit to the first 1100 days of data. In all four channels, the photometry is consistent with a linear decrease in flux for the first three years of the mission, followed by a rapid decrease in flux of $\approx 2.5\%$ over the next six months. The light gray curve represents one possible *Kepler* long cadence light curve consistent with the FFI photometry created by fitting a spline to the FFI photometry as described in Section 4. The large dips observed by Boyajian et al. (2016) are visible but narrow relative to the cadence of FFI observations. The long cadence data behind this figure are available online.

TABLE 1
FFI DATA

jitter in radial velocity (RV) observations (Butler et al. 1996). Including a slope and zeropoint for the linear fit, there are a total of nine free parameters.

By marginalizing over all parameters except the slope, we can measure the decay rate of the observed flux. We determine that the star is fading from our perspective at a rate of $0.341 \pm 0.041\%$ yr^{-1} , or 3.41 ± 0.41 parts per thousand (ppt) yr^{-1} . This is equivalent to fading at a rate of 0.370 ± 0.044 magnitudes per century, exceeding the purported 0.165 mag century $^{-1}$ ($0.152 \pm 0.012\%$ yr^{-1}) rate of dimming over the duration of the DASCH plates (Schaefer 2016) by more than a factor of two. The total change in brightness over this portion of the *Kepler* light curve is almost 1%.

3.2. A Rapid Dimming

Beginning around MJD–2454833 \sim 1100, lasting for approximately 200 days, the rate of dimming increases dramatically. Repeating the above exercise in the region between dates 1100 and 1250, we measure a decay rate of $3.37 \pm 1.48\%$ yr^{-1} . Here, we allow the break points at which the slope changes to float as free parameters, and the uncertainty in the actual dimming rate during this event is dominated by the uncertainty in the exact timing of the change in slope. Regardless of the exact rate at which the star appears to dim from our line of sight, it is clear that from the *Kepler* data, the star becomes approximately 2.5% dimmer over a period of 200 days. This rapid dimming is apparent in data from all four orientations of the *Kepler* spacecraft. We note we would expect the *Kepler* pre-search data conditioning (PDC) pipeline to remove signals such as this one in the pre-processing of the data, explaining why this signal does not appear in the originally published long-cadence light curve.

After the conclusion of this event, there are only nine epochs of FFI data. Over this range, the rate of change of flux from the star is poorly measured: it is consistent with the original rate of dimming, but also consistent with a flat light curve until the final FFI image is collected at the end of Quarter 16 of the *Kepler* mission.

We offer no definitive explanation that could explain the observed light curve in this work. The effect could be stellar in nature, although there are no known mechanisms that would cause a main-sequence F star to dim in brightness by 2.5% over a few months. The effect could also be caused by a passing dust cloud in orbit around KIC 8462852. Indeed, the light curve at times larger than 1000 days has a morphology broadly similar to a transit event, although on markedly different timescales. We discuss this morphology more fully in Section 5.4.

3.3. Comparison with Dimming Events

The long-cadence light curve as observed by *Kepler* contains features in which the observed flux from the star decreases by as much as 20% for a few days at a time. Our results could be substantially affected if any of these events were to overlap with the collection of a full frame image. We can test this possibility by comparing the times recorded for the FFI data with the largest dipping events in the *Kepler* light curve. The result is shown in Figure 4.

We find that the dips do not overlap with any of the FFI observations. The only FFI image that is sufficiently close to a dipping event to possibly be affected is the final FFI of Quarter 8. If we repeat our analysis removing this data point, we recover the same long-term dimming; none of the results in this work are significantly affected by the inclusion or exclusion of this single data point.

As can be seen in Figure 1b of Boyajian et al. (2016), some of the dipping events are surrounded by apparent flux increases of $\sim 0.1\%$. If these increases are real, they could be the signature of forward scattering from dust grains (e.g., Rappaport et al. 2012). Most notably, the PDC light curve produced by the *Kepler* mission appears to rise just before a 15% dip. This particular FFI frame records a lower flux value than its predecessor by approximately 1 mmag, although the two are consistent with no change in flux. To test whether the small rise in the PDC light curve is induced by the initial data pro-

FIG. 4.— Times of FFI data collection superimposed on the *Kepler* long cadence light curve of KIC 8462852. Each vertical line represents the time of capture of an FFI, with the colors retaining their same meaning as in Figure 3. None of the FFIs are taken during a dip that could significantly affect our photometry. We produce our own long cadence light curve as explained in Section 3.3, finding no evidence for the rise before the dip at the end of Quarter 8 observed in the PDC light curve.

cessing in the creation of the PDC light curves or if it is real, we create our own long cadence light curve from the pixel-level data. We perform aperture photometry using the entire postage stamp downloaded by the *Kepler* mission, not just the smaller aperture selected by the *Kepler* team for the creation of SAP and PDC light curves. We do the same for KIC 8462934, the single star within 2 arcmin with K_p within one magnitude of KIC 8462852. We then divide the flux recorded for KIC 8462852 by the flux recorded by its apparent neighbor to account for instrumental trends.

The rise in the PDC light curve in Q8 does not exist in this light curve, suggesting that it is an artifact of the processing in the development of the PDC light curve. Similarly, the rise in the light curve at Day 1148, observed in the PDC light curve and this light curve, is almost certainly an artifact of data processing. There are also small rises observed before the dips at dates 140 and 260. We note that these also occur immediately after data downlinks, as the telescope is reestablishing thermal balance after rotating to point to earth and changing the position of its heat shields. It is well established that this maneuver leads to a ramp in the observed flux lasting ≈ 3 days after observations resume (Smith et al. 2012). As both rises occur during these windows, it is likely that they are induced by these thermal effects. There is a small rise (≈ 2 mmag) observed at the end of Quarter 13 that may be real; it appears at low significance in the FFI data as well.

In the full light curves, we detect a significant variation in the total flux received from quarter to quarter, a sign of changes in the underlying flat field from channel to channel. For each quarter, we allow a multiplicative off-

set to minimize the variation between quarters. Still, the paucity of nearby reference stars means that long-term trends cannot be robustly detected in the long-cadence data. In this case, for the purposes of plotting we remove long-term trends. We divide the light curve into distinct regions separated by gaps in the data of at least 0.5 days. We then mask the regions of the light curve identified as short-term dips by Boyajian et al. (2012) and fit a spline to the remainder of the data, dividing the measured light curve by the spline to flatten the light curve. The result is a normalized light curve that removes trends but preserves the shape and magnitude of the rapid dips. These data are shown in Figure 4 and we make them publicly available.⁴

As the FFI data provide absolute calibration of the *Kepler* data once per month, the FFI data can be combined with the *Kepler* long cadence light curve to show one plausible iteration of the true photometric variability of KIC 8462852. To create this light curve, we fit a cubic spline to the FFI data using the spline tool in `scipy.optimize`. We use the measured photometric precision for each FFI as the input weights. We apply a smoothing factor of 40. These data are plotted in Figure 3 and included in the same data file as the previously described light curves. As the data are not calibrated between the FFIs, and each FFI observation has an associated photometric uncertainty, this long cadence light curve only represents one possible realization of the photometric variability of KIC 8462852 and should only be considered in that context.

FFI images are typically collected as the last observation of a month of continuous data collection immediately before data downlink to Earth. After the FFI is taken, there is typically a ≈ 1 day gap before data collection is resumed. It is unlikely that a large dip could fall in one of these gaps while evading detection in the long cadence data, as the ingress duration for a dip would need to be smaller than the 30 minutes between the last long cadence image of a single month and the FFI collected immediately afterward.

4. COMPARISON TO OTHER *KEPLER* STARS

The long-term dimming of KIC 8462852 observed during the first 12 quarters of the *Kepler* mission differs from zero by 8σ . In modeling the light curve, we assumed that the sources of uncertainty are entirely statistical in nature. If there are other, long-term systematics that cause a slow drift in the recorded *Kepler* flux from a star, those could evade our statistical analysis and cause us to erroneously record a long-term trend that does not exist. If such systematics exist, their effect should be detectable for many stars, so we can compare the observed light curve in our analysis with other stars in the *Kepler* field to see how often a star exhibits a dimming of $0.341 \pm 0.041\%$ yr^{-1} .

4.1. Reference Stars

We repeat the analysis in Section 3, performing photometry on other stars that fall onto the 8×8 arcminute postcard around KIC 8462852. If long-term trends of a similar magnitude are recovered in any of these, it is an

⁴ http://www.astro.caltech.edu/~btm/kic8462852/reduced_lc.txt

indication that the *Kepler* photometry is dominated by systematics from one or a few active stars in particular.

FIG. 5.— Photometry for eight stars produced in the same method as described in Section 2. These stars all have $11 < K_p < 14.5$ and are located within $4'$ of KIC 8462852 on the sky. In no cases do we detect a similar dimming to that observed for KIC 8462852, suggesting the dimming is not caused by systematics due to variability of nearby reference stars.

To test for systematics, we repeat our process to develop light curves for eight other stars, all with $11 < K_p < 14.5$ and all located within $4'$ (60 pixels) of KIC 8462852 on the sky. In these cases, KIC 8462852 was not selected by our pipeline as a potential reference star due to its photometric variability relative to the other nearby stars.

The photometry for these stars is shown in Figure 5. None of these stars exhibit a large offset in either direction around 1100 days into the mission, at the time of the rapid change in flux of KIC 8462852. We can fit a long-term trend to each of these stars to measure the photometric long-term variability as recorded by *Kepler*. In practice, we fit five parameters: a slope, a zeropoint, and three relative offsets between observing seasons as the star falls on different detectors, maximizing the likelihood of this model to the data. We also inspect each light curve by eye to look for significant deviations from non-linearity similar to that detected for KIC 8462852.

For none of these stars do we recover a slope as extreme as 3.41 ± 0.41 ppt yr $^{-1}$. Similarly, we do not detect any 2.5% decreases in flux between days 1100 and 1200 (or at any other time), suggesting that this effect observed in the light curve of KIC 8462852 is not due to a spurious reference star, nor is there a systematic effect in all nearby stars. We do note that we recover the same changes in photometric precision as observed for KIC 8462852 as the stars move from one detector to the next while the spacecraft rolls during its orbit.

4.2. Other Nearby Stars

We can extend our analysis to search for variations in not only the most nearby stars used as reference stars,

but to all stars on the same detector. We select all stars with K_p within 0.5 mag of KIC 8462852 and located in the same “skygroup,” meaning they all fall on the same channel at the same time. We remove stars that would not be expected to provide reliable tests in a search for systematic trends in the *Kepler* data, including known variable stars, eclipsing binaries, and those with starspot-induced variability at the level of 1% or more through a visual inspection of the long cadence light curves. These cuts leave 193 viable stars against which to compare.

We find, of these 193 stars, for only one do we measure a long-term trend: KIC 8395126 appears to decrease in brightness over the *Kepler* mission, with a maximum likelihood measurement of the slope of 3.9 ppt yr $^{-1}$. The measurements of the maximum likelihood slopes for the full sample of 193 nearby stars, again fitting for a slope and four offset terms, are distributed with a mean of -0.16 ppt yr $^{-1}$ and a standard deviation of 1.23 ppt yr $^{-1}$. We plot a kernel density estimator (KDE) of the distribution of fitted slopes in Figure 6. For all cases, we apply a Gaussian kernel with a bandwidth of 0.41 ppt yr $^{-1}$ — equal to the uncertainty in the measured Q0-Q12 slope for KIC 8462852 and a reasonable estimate of the typical measurement uncertainty.

We find that only 0.5% of the mass of the KDE is located at variations equal to or larger than the maximum likelihood value of the slope of 3.41 ppt yr $^{-1}$ recorded over the first three years of the *Kepler* mission for KIC 8462852. Moreover, there is no mass at 7.8 ppt yr $^{-1}$, the value recovered if one were to blindly fit a linear model to the distinctly non-linear light curve for KIC 8462852. In no cases do we observe a 2.5% dip over 6 months as observed for KIC 8462852.

4.3. Other *F* stars

We can also compare the flux variations observed for KIC 8462852 to FFI light curves for stars of similar spectral types. Here, we use the sample of KIC stars developed by Lund et al. (2016) and considered in their analysis of the DASCH plates. In that work, the authors selected 559 stars listed in the updated Kepler Input Catalog (Huber et al. 2014) with inferred stellar effective temperatures within 100 K, radii within 5%, and $\log g$ within 10% of KIC 8462852.

From this sample, we remove all stars for which we do not expect to acquire reliable photometry or observe long-term photometric trends over four-year baselines. We remove stars with brighter neighbors located within ten pixels of the target star, so that their flux is likely to leak into our own aperture. We also remove stars near the edge of the detector and stars that do not fall onto the *Kepler* detectors in at least three of the four observing seasons. We remove stars that saturate the detector, and also those that are intrinsically variable, including contact binaries, stars that vary due to spots at larger than the 2% level, and pulsating variable stars. We note that the two targets that Lund et al. (2016) noted as long-term variable, KIC 3868420 and KIC 11802860, both are removed by this last requirement. The former exhibits 15% variability with a five hour period in the *Kepler* light curve; Nemec et al. (2013) suggest it may be a high-amplitude Delta Scuti. The latter exhibits 40% variability with a 16.5 hour period in its *Kepler* light curve; the star is also known as AW Dra and has long

been known as an RR Lyrae (Castellani et al. 1998).

The long-term variability observed by Lund et al. may be the result of unfortunate timing of the observations across different phases of the star’s light curve, causing an apparent long-term trend. This is plausible as the claimed photometric trends have different signs in the pre- and post-1970 subsets of the DASCH data. The long-term variability could also be a case of rapid stellar evolution: Stellingwerf (2013) suggest RR Lyrae stars may be undergoing rapid mass-loss, which may lead to a dimming over a timescale of decades.

We note that the overall distribution of F star variability is well-approximated by a Gaussian with mean -0.065 ppt yr $^{-1}$ and standard deviation 0.094 ppt yr $^{-1}$. Stellar evolution does not explain a long-term trend in the typical F star; detection of a nonzero mean dimming is likely indicative of a systematic in the *Kepler* data that is not understood. We repeat our KDE analysis of these stars from the previous analysis, finding 0.7% of the KDE mass is located at variations larger than the maximum likelihood slope for KIC 8462852 from the first three years of the *Kepler* mission. Again, there is no mass at 7.8 ppt yr $^{-1}$, and in no cases do we detect a 2.5% dip over six months; of all stars analyzed in this work, the rapid dimming between quarters 12 and 15 appears to be unique to KIC 8462852.

FIG. 6.— Kernel density estimator of the distribution of measured linear changes of the brightness of other stars observed in the *Kepler* FFIs. The red curve represents an analysis of other stars with similar properties to KIC 8462852; the blue represents stars of similar magnitude on the same channel of the detector. The bandwidth chosen in the creation of the KDE is equivalent to the uncertainty in the linear fit to the photometry of KIC 8462852 over the first three years of the mission. We find 0.7% (0.5%) of the mass of the KDE representing stars with similar properties (similar locations) is located at variations larger than those observed in the first three years of the light curve of KIC 8462852 (represented with a black arrow). No stars in the comparison sample produce slopes as large as would be measured by a simple linear fit to the full FFI light curve for our target (represented with a larger black arrow), nor do we observe a rapid 2.5% decrease in flux for any of these stars.

5. DISCUSSION

The *Kepler* FFI light curve for KIC 8462852 features a long-term slow dimming over the first three years of the mission. Formally, the observed slope is statistically significant, but approximately 0.5% of a sample of stars

stars near the target star spatially and 0.7% of a sample of stars with similar stellar classification exhibit a slope that is at least as large in magnitude as the one observed here. Using these other stars as a proxy for systematics that could induce long-term drifts in the photometry of a single star, the dimming of KIC 8462852 over the first three years of the *Kepler* mission is a 2.7σ event.

However, there are no stars that we detect that exhibit a 7.8 ppt yr $^{-1}$ dimming, the level that a simple linear model would produce when fit to the full, nonlinear data set. Additionally, there are no stars that exhibit a 2.5% decrement in flux over approximately six months, suggesting this star is indeed undergoing some process leading to a decrease in its brightness over the span of the *Kepler* mission. In the remainder of this section we consider possible interpretations of this result.

5.1. Comparison to DASCH Photometry

As mentioned in Section 1, Schaefer (2016) used 99 years of photometry from the DASCH project to analyze the behavior of KIC 8462852, finding a decrease in brightness of 14% from 1890 to 1989. Hippke et al. (2016) performed an independent analysis of the DASCH photometry, confirming that the photographic data yield a fainter magnitude for KIC 8462852 in the late 20th century compared to the end of the 19th century. However, Hippke et al. argue that the DASCH measurements from 1890 to 1952 are best described by a constant brightness and measurements from 1967 to 1989 are best described by a different (fainter) constant brightness, with systematic errors accounting for the offset.

We attempt to reproduce both results (for KIC 8462852 only, not the comparison stars). We find that either a linear decline in brightness with time or a constant brightness with a systematic offset between pre-1952 and post-1967 observations is a reasonable description of the DASCH measurements. The unfortunate gap of 15 years with very few observations in the middle of the century makes it difficult to distinguish between the two models. Which explanation to prefer then depends on one’s assessment of whether a star steadily fading for a century or a change in the photometric calibration of the Harvard plates around 1962 is more likely (or less unlikely). The fading that we detect from 2009 to 2013 with the *Kepler* FFI images does not necessarily represent a confirmation that KIC 8462852 also dimmed over the preceding 129 yr, but could make that interpretation of the DASCH data more plausible.

5.2. Instrumental Effects

The observed dimming does not seem to be associated with any instrumental effect. Some known effects could cause a 2.5% decrement in the observed flux from a star. The most common such effect is a Sudden Pixel Sensitivity Dropout (SPSD), in which a pixel abruptly decreases in sensitivity, leading to a decrease in the observed flux on that pixel. The pixel generally recovers in sensitivity over a few hours, but does not return to the same sensitivity level as before (Smith et al. 2012). An SPSP could not explain our observed light curve, as the observed flux decrement is visible in all four detector orientations, so the same SPSP would have had to occur on all four apertures, at the same level, at approximately the same time.

Similarly, we do not expect this effect to be the result of any calibration issues during the processing of the FFIs. The calibration pipeline accounts for the bias and dark current of the detector, cosmic rays, smearing effects from reading out without a shutter, and distortions induced from the readout electronics (Quintana et al. 2010). Most of these effects are dependent on the location of the star, rather than the physical properties of the star itself, so we would not expect them to induce a dimming observed over all four modules. The exception is the smear correction, but the smear is well-understood and can be robustly estimated from the data. Significant errors in the smear correction would be easily observable in the FFI data itself as “trails” in the FFI image near the star, which are not detected in these observations.

5.3. Background Contamination

Approximately 25 arcsec from KIC 8462852 is KIC 8462860, a star 3.65 magnitudes fainter on the edge of our photometric aperture. As approximately half of the star falls in our simple aperture, we would expect it to contribute approximately 1.8% of the total flux in our aperture. This star cannot explain the long-term trend over the first three years of the mission unless it were to decrease in flux by 50%; it cannot explain the rapid dimming event unless it disappeared entirely (which is obviously not the case).

KIC 8462860 could explain the observed rapid dimming if the star had a large proper motion and moved out of the aperture during Quarters 13 and 14. However, in the PPMXL catalog (Roesser et al. 2010) its proper motion is $\mu_{\text{RA}} = 2.4 \pm 4.1 \text{ mas yr}^{-1}$, $\mu_{\text{Dec}} = 0.3 \pm 4.1 \text{ mas yr}^{-1}$. The star is listed in the KIC as having a temperature of 5464 K, and its magnitude and colors ($m_r = 15.6$, $r - J = 1.4$, $J - K = 0.5$) are broadly consistent with a late G or early K dwarf at several hundred parsec or an evolved G/K star at larger distances. The photometry is not consistent with what would be expected of a nearby star.

If the star did have a large proper motion, we would see it move by several pixels over the course of the mission, which visual inspection of the FFI data does not show. Moreover, to move far enough so that the entire core of the PSF moved across the edge of our aperture over a span of approximately six months, the proper motion would need to be approaching $10 \text{ arcsec yr}^{-1}$. In this case, we would expect the star to traverse the entire aperture over the four years of FFI data, which we do not observe.

Perhaps most significantly, the same light curve as shown in Figure 3 is recovered when we mask the pixels corresponding to KIC 8462860, or if we modify the size of our aperture to either move this other star fully inside or outside of the aperture rather than on the edge. Therefore, we can exclude the possibility that the observed variations in the light curve are caused by the presence of KIC 8462860. Moreover, we do not detect the presence of any centroid shifts correlated with the measured flux in the light curve of this star, suggesting this result is not the effect of the neighboring star or changes in the underlying flat field.

5.4. Transiting Material

We note that the shape of the light curve after Quarter 12 appears broadly similar to that of a transit event. Over six months, the rapid dimming could represent the ingress of material blocking the stellar disk, leading to a decrease in observed flux. The primary mission then ends before third contact is observed. Clouds of transiting material due to disintegrating bodies have been observed in *Kepler* data, but only with very short orbital periods (Rappaport et al. 2014; Sanchis-Ojeda et al. 2015). In the case of KIC 8462852, there are problems with this model. First, it does not explain the observed long-term dimming over the first three years of the *Kepler* mission, nor does it explain the long-term trend observed over the past 100 years through the DASCH data. A single transit model also does not explain the phenomena observed by Boyajian et al. (2016), especially those dips before the time of ingress. Nevertheless, we investigate whether it is a possible explanation for the rapid dimming.

A transit event with a timescale similar to that observed here is not unprecedented. ϵ Aurigae is transited every 27 years, with a transit lasting approximately 1.5 years (Kopal 1954; Huang 1965). Recently, Rodriguez et al. (2016) observed transits of TYC 2505-672-1 with a period of 69.1 years and a duration of 3.45 years. In both cases, the primary is orbited by a hot source that hosts an extended disk of circumstellar material. Kloppeborg et al. (2010) confirmed this model with closure-phase interferometric imaging, directly imaging the disk occulting ϵ Aurigae.

For both ϵ Aurigae and TYC 2505-672-1, the disk is optically thick and circumstellar around a binary companion. The sub-millimeter observations of Thompson et al. (2016) place a limit of $7.7 M_{\oplus}$ of material within 200 AU of KIC 8462852, ruling out a direct analogue of these other systems.

First, we consider that this signal represents the transit of a solid body across the stellar disk of KIC 8462852. In this scenario the observed timescales of the event constrain the size and distance of the eclipsing object. For an optically thick transiting object, the 2.5% transit depth indicates a minimum radius of $0.15 R_{\star}$ (Boyajian et al. 2016 estimate a radius of $1.58 R_{\odot}$ for KIC 8462852). If the transiting body is in a Keplerian orbit, the extremely slow ingress time and long transit duration place it at the implausibly large distance of $\sim 10 \text{ pc}$, with a transit probability of $\sim 10^{-9}$. Note that while a six-month transit ingress and transit duration of more than six months is similar to ϵ Aurigae and TYC 2505-672-1, this case is distinct from those because of the much smaller radius of KIC 8462852. The transit of a main sequence star is necessarily much shorter than that of a supergiant with $R \gtrsim 50 R_{\odot}$. Even if every star had a companion at 10 pc, then given 10^4 *Kepler* missions we would expect to observe one such transit event; we can confidently disfavor this hypothesis.

If the transiting material is instead an optically thin cloud, then its size could be comparable to or larger than that of KIC 8462852. The optical depth of such a cloud would be $\tau \approx 0.025$. Because the orbiting body considered in the previous paragraph was already a significant fraction of the stellar radius, though, a much bigger cloud does not qualitatively change the result: in order for the transit ingress to last $\sim 180 \text{ d}$, a cloud in a Keplerian orbit would need to be located $\gtrsim 1 \text{ pc}$ away from the

star. We thus conclude that a simple transit of any kind of orbiting object is not a reasonable explanation for the rapid fading that begins in Quarter 12. However, this conclusion relies on the assumption that the duration of the transit ingress is set by the orbital velocity of the transiting body.

More complex scenarios in which the ingress timescale reflects the spreading of debris along its orbit after a recent collision or the precession of an occulting disk into our line of sight could perhaps explain the appearance of a transit. For example, a cloud that slowly increases in density would manifest itself in the light curve as inducing a change in flux similar to that observed in Quarter 12. However, to produce the apparent flat bottom of the supposed transit event, such a cloud would then need to be extended over a fraction of its Keplerian orbit and would need to maintain an approximately constant density through its entire length as it passes in front of this star.

It is very difficult to come up with a physical model that can even qualitatively explain all of the major features of KIC 8462852’s photometric behavior simultaneously. Of the ideas that have been proposed so far, we suggest that the most promising explanation involves a recent collision between large bodies (planetesimals or comets) in the KIC 8462852 system, leading to a spreading of debris as in the previous paragraph. In this picture, a recent collision could create a cloud of circumstellar material and push a family of objects into a highly eccentric orbit, analogous to the period of late heavy bombardment observed in our own solar system. However, this idea does not naturally account for the steady decline in the flux of KIC 8462852 in the years preceding the more rapid dimming and the concentrated sequence of dips. The data presented in this paper cannot fully exclude any of these models, but we note that the circumstellar dust and debris produced by such an event is unlikely to maintain this arrangement for long timescales. The sub-mm limits of Thompson et al. (2016) and continued photometric monitoring will significantly constrain future models that attempt to invoke circumstellar dust or transiting models to explain this light curve.

5.5. A Polar Spot

Under certain conditions, a long-lasting spot growing at polar latitudes on the surface of KIC 8462852 could possibly reproduce the long-term light curve observed here. While polar spots have not previously been detected on an F3V dwarf star, they have been observed on the surface of an F9V star, albeit one in a tight (1.15 day) binary with another stellar companion (Strassmeier & Rice 2003). Through Doppler tomography observations, polar spots on more massive stars have been seen to evolve on similar timescales to the flux variability observed here (Roettenbacher et al. 2016).

For a polar spot to create the observed decrease in flux in the light curve, the star would need to be at a low enough inclination so that the pole is always visible. Boyajian et al. (2016) measure a rotation period and $v \sin i$ of the star and combine these with an estimate of the radius to infer an inclination of 68 ± 29 degrees at 68% confidence, leaving open the possibility that the pole can indeed be observed at all times.

If a spot were growing near the polar latitudes of the

surface of the star between Quarters 13 and 15, we might expect a corresponding increase in overall magnetic activity, leading to an increase in starspots at other latitudes over this time period. This appears to be the case. Boyajian et al. (2016) measure a periodic signal with a period of 0.88 days, as well as additional signals at 0.90 and 0.96 days, all of which change in intensity during the *Kepler* mission. The authors suggest this signal may be induced by starspots. Spots at different latitudes evolving and rotating differentially would produce a signal like this one. The strength of the signal they observe grows between days 1100 and 1300 of the mission, suggesting either an increase in the number of spots or an increase in their coherence. Interestingly, the growth of the signal corresponds to the time of rapid decrease in total flux recorded in the FFI images.

The inclination of KIC 8462852 and the coincidence between the spot activity and the rapid dimming do not present a confirmation of a polar spot. A long-lasting polar spot itself would be remarkable given the F3V spectral type of the star, but with the current data the hypothesis cannot be excluded. Broadly, the FFI observations are consistent with the growth of a polar spot that grows at a similar time to the growth of spots at lower latitudes. Spots, however, can not explain the short-term dips originally observed by Boyajian et al. (2016). More observations are needed to separate the spot hypothesis from other possible explanations of the observed light curve.

5.6. Additional Observations

In this work, we do not present a model that can explain the entire suite of observations of KIC 8462852. There are now three distinct photometric variations observed: rapid, irregular decreases of 10% or more in flux lasting for a few days, a 2.5% decrease in flux lasting for at least one year, and a likely long-term dimming perhaps spanning more than a century. Additional observations would be helpful in order to better understand physical phenomena that could cause any or all of these events.

Multi-color photometry is essential to help characterize this star. If any of these events are caused by solid bodies, we would expect the photometric variations to be largely achromatic. However, if they are caused by a cloud of dust and gas, we would expect the cloud to redden the star. Similarly, spots with a lower effective temperature than the rest of the stellar surface would cause an apparent change in the color of the star as they cover more of the stellar disc. A transiting cloud would be expected to induce dips that are largely periodic, while changes in the spot patterns would not necessarily be periodic. High precision observations of the color of KIC 8462852 over time could explain the nature of each of these events, supporting or ruling out the transiting cloud or spot hypotheses. Similarly, additional IR and sub-mm observations of the system could be used to place tighter upper limits on the amount of circumstellar material surrounding the star.

Additional radial velocity (RV) monitoring to search for companions in few-AU orbits around the star, especially those that could hold together a disk of circumstellar material into a gravitationally bound system, would also be useful. Boyajian et al. (2016) obtained four high resolution spectra over the course of approximately 500

days. The measured RV of KIC 8462852 in these observations has a scatter of 0.3 km s^{-1} and each observation has a precision of 0.4 km s^{-1} . While the data are consistent with no RV variations, continued monitoring could detect the presence of massive companions on wider orbits. High resolution spectra could also be used to probe any evolution in the magnetic activity of the star correlated with the growth or decay of spots.

6. CONCLUSIONS

Recently, multiple analyses of DASCH photometry have produced conflicting results about the possible detection of a long-term dimming of KIC 8462852 by 0.165 ± 0.013 magnitudes over the 20th century, or $0.152 \pm 0.012\% \text{ yr}^{-1}$. The dimming of a star at that rate should be detectable in *Kepler* data. Here, we analyze monthly *Kepler* FFI images to search for similar dimming in the FFI light curve of KIC 8462852.

We perform aperture photometry on KIC 8462852 and seven nearby comparison stars. We observe that during the first three years of the *Kepler* mission, the star dimmed at a rate of $0.341 \pm 0.041\% \text{ yr}^{-1}$. Over the following 6 months, the star decreased in brightness by 2.5%, then remained at that level for the duration of the primary *Kepler* mission. This result is not sensitive to the size of the chosen aperture or the particular choice of reference stars.

We then compare this result to a similar analysis of other stars of similar brightness on the same detector, as well as stars with similar stellar properties, as listed in the KIC, in the *Kepler* field. We find that 0.5% of stars on the same detector and 0.7% of stars with similar stellar properties exhibit a long-term trend consistent with that observed for KIC 8462852 during the first three years of the *Kepler* mission. However, in no cases do we observe a flux decrement as extreme as the 2.5% dip observed in Quarters 12-14 of the mission. The total brightness change of KIC 8462852 is also larger than that of any other star we have identified in the *Kepler* images.

Broadly speaking, the morphology of the light curve is generally consistent with the transit of a cloud of optically thick material orbiting the star. Such a dust cloud could be small enough to evade submillimeter detection in the analysis of Thompson et al. (2016), who place a limit of $7.7 M_{\oplus}$ of material orbiting KIC 8462852. The breakup of a small body or a recent collision that could produce a cloud of material could also plausibly produce a family of comets that transit the host star together

as one group (Bodman & Quillen 2016), explaining the light curve observed by Boyajian et al. (2016). However, in order to match the observed time of ingress and transit duration, some fine-tuning is required. To explain the transit ingress timescale, the cloud would need to be at impossibly large distances from the star or be slowly increasing in surface density. The flat bottom of the transit would then suggest a rapid transition into a region of uniform density in the cloud, which then continues to transit the star for at least the next year of the *Kepler* mission. Moreover, such a model does not naturally account for the long-term dimming in the light curve observed in both DASCH and the *Kepler* FFI data, suggesting that this idea is, at best, incomplete. We strongly encourage further refinements, alternative hypotheses, and new data in order to explain the full suite of observations of this very mysterious object.

Facility: Kepler

We thank Jason Dittmann and Jieun Choi (Harvard) for conversations about data analysis and figure design that improved the quality of this paper. We also thank Rachael Roettenbacher (Stockholm University) and John Johnson (Harvard) for discussions of starspots, Ryan Foley (Univ. of Illinois) for initial conversations about photometry and the DASCH results, George Preston (Carnegie) for insights into variable stars, and Eugene Chiang (UC Berkeley) and Jason Wright (Penn State) for ideas about other potentially similar systems.

STScI is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. Support for MAST for non-HST data is provided by the NASA Office of Space Science via grant NNX09AF08G and by other grants and contracts.

This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France and NASA's Astrophysics Data System.
